

## 4.60 neodymium

Stable isotope	Relative atomic mass	Mole fraction
$^{142}\text{Nd}$	141.907 73	0.271 53
$^{143}\text{Nd}$	142.909 82	0.121 73
$^{144}\text{Nd}^\dagger$	143.910 09	0.237 98
$^{145}\text{Nd}$	144.912 58	0.082 93
$^{146}\text{Nd}$	145.913 12	0.171 89
$^{148}\text{Nd}$	147.916 90	0.057 56
$^{150}\text{Nd}^\dagger$	149.920 90	0.056 38

$^\dagger$  **Radioactive isotope** having a relatively long **half-life** and a characteristic terrestrial **isotopic abundance** that contributes significantly and reproducibly to the determination of the **standard atomic weight** of the **element in normal materials**. The half-lives of  $^{144}\text{Nd}$  and  $^{150}\text{Nd}$  are  $2.1 \times 10^{15}$  years and  $1.3 \times 10^{20}$  years, respectively.

## Half-life of radioactive isotope

Less than 1 hour   
Between 1 hour and 1 year   
Greater than 1 year 

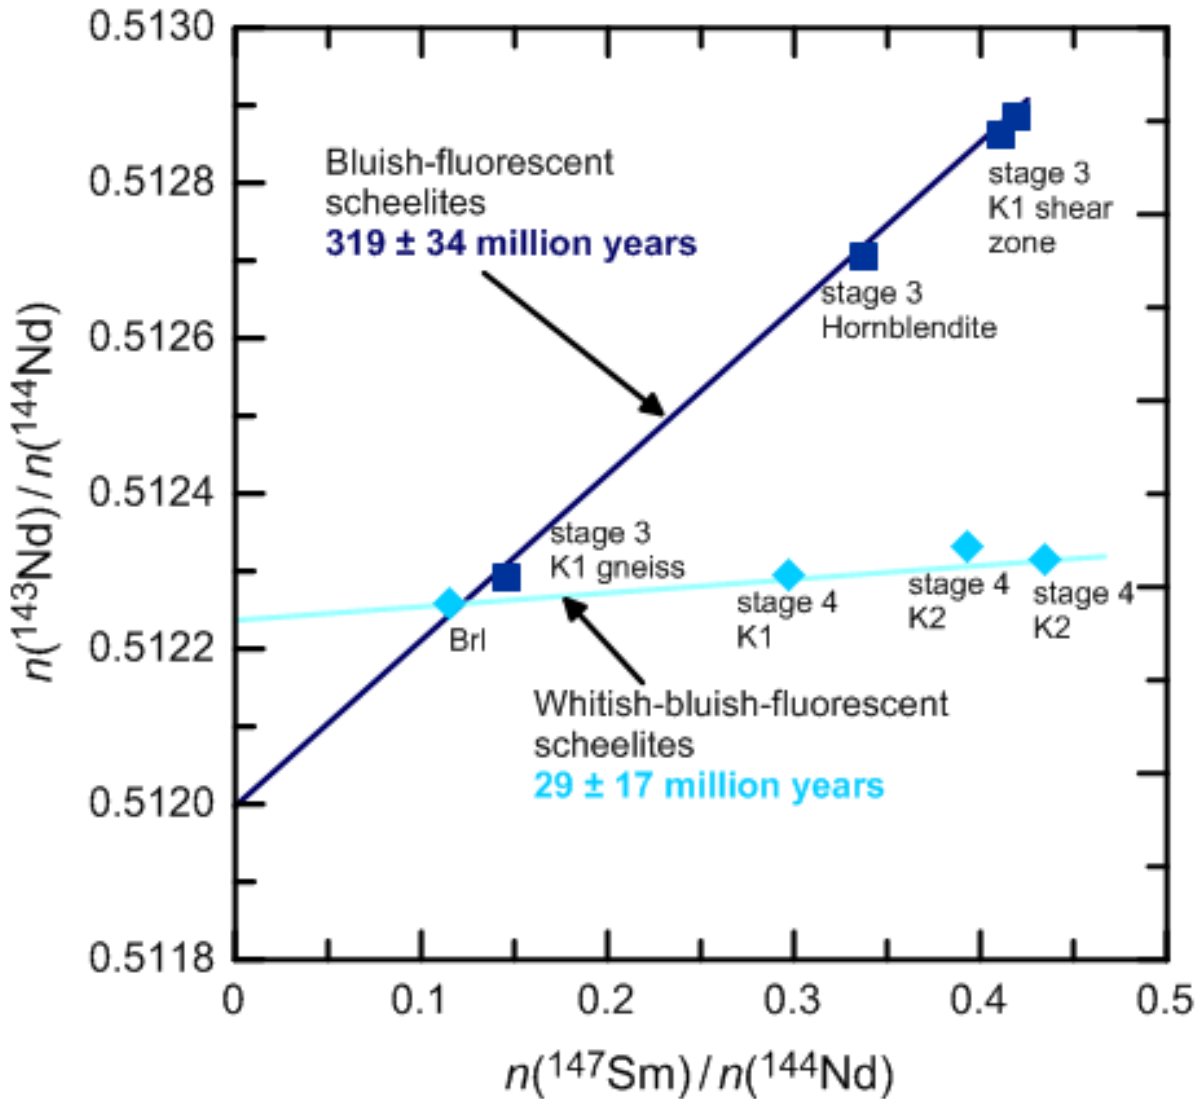

## 4.60.1 Neodymium isotopes in geochronology

$^{143}\text{Nd}$  is a **radiogenic isotope** produced by decay of  $^{147}\text{Sm}$ , with a **half-life** of  $1.06 \times 10^{11}$  years. Thus, the **isotope-amount ratio**  $n(^{143}\text{Nd})/n(^{144}\text{Nd})$  can be used for dating rocks on long time

IUPAC

1 scales and as a chemical **tracer** in geochemistry (Figure 4.60.1) [424, 425]. The very small  
 2 accumulation of  $^{142}\text{Nd}$  in billion-year-old metamorphosed rocks from Greenland [from the

3  
 4  
 5 **Fig. 4.60.1:** Cross plot of  $n(^{143}\text{Nd})/n(^{144}\text{Nd})$  **isotope-amount ratio** and  $n(^{147}\text{Sm})/n(^{144}\text{Nd})$  **mole**  
 6 **ratio** for two periods of scheelite (calcium tungstate; ore of tungsten) mineralization  
 7 (metamorphism) (modified from [425]).  $^{143}\text{Nd}$  is produced by decay of  $^{147}\text{Sm}$ . Rock containing  
 8 higher amounts of  $^{147}\text{Sm}$  at time of mineralization will over time produce higher amounts of  
 9  $^{143}\text{Nd}$  (e.g., sample stage 3 K1 shear zone and sample stage 4 K2). Alternatively, rocks  
 10 containing lower amounts of  $^{147}\text{Sm}$  at time of mineralization will over time produce lower  
 11 amounts of  $^{143}\text{Nd}$  (e.g., sample stage 3 K1 gneiss and sample Brl). Samples from an older  
 12 mineralization event will have proportionally more  $^{143}\text{Nd}$  because of the longer accumulation  
 13 time for  $^{143}\text{Nd}$ ; thus, the line through the bluish-fluorescent scheelites with an age of  $319 \pm$   
 14  $34 \times 10^6$  years has a substantially higher slope than the line through the whitish-bluish-  
 15 fluorescent scheelites with an age of  $29 \pm 17 \times 10^6$  years. These lines from which age of  
 16 mineralization (crystallization) can be determined are called **isochrons**.

## IUPAC

1  
2  
3 relatively short-lived ( $\sim 68 \times 10^6$  years) **alpha decay** of  $^{146}\text{Sm}$ ] provided evidence that the crust  
4 of the Earth formed before the young planet was more than  $100 \times 10^6$  years old. This is because  
5 only a short amount of time could have elapsed to incorporate the  $^{146}\text{Sm}$  **parent radionuclide** into  
6 the ancient Greenland minerals before it decayed [426, 427].

### 7 **4.60.2 Neodymium isotopes used as a source of radioactive isotope(s)**

8  $^{146}\text{Nd}$  has been used in the production of  $^{147}\text{Pm}$  (with a half-life of 2.6 years), via the  $^{146}\text{Nd} (n, \gamma)$   
9  $^{147}\text{Nd} \rightarrow ^{147}\text{Pm}$  reaction, which is a radioisotopic power-generation source [428].
